The COVID-19 Vaccine and Cancer: FREQUENTLY ASKED QUESTIONS

The following are frequently asked questions about the COVID-19 vaccine and adult cancer patients. The information is:

- related to the Pfizer and the Moderna COVID-19 vaccines that use mRNA technology
- related to the AstraZeneca COVID-19* vaccine that uses non-replicating viral vectors (adenovirus)
- current as of September 14, 2021

The information below may not be appropriate for all patients. Prescribers must determine whether adopting suggested COVID-19 vaccine information is clinically appropriate for individual patients through a risk-benefit assessment. Consult appropriate clinical prescribing guidelines and local institutional guidance for patient prioritization to inform treatment and vaccination decisions.

Everyone should receive a COVID-19 vaccination, when available, unless contraindicated. See question 2 “What are the contraindications to the COVID-19 vaccines?” for more information. There are limitations to the current knowledge around the use of COVID-19 vaccines in the cancer population. The advice below is based on the best available evidence at this time. Guidance will be updated as more evidence becomes available.

Patients should continue to practice recommended public health measures for prevention of COVID-19 infection regardless of vaccination status.

* Note that COVISHIELD (manufactured by Serum Institute of India) and the AstraZeneca COVID-19 vaccine (manufactured by AstraZeneca) are ChAdOx1-S recombinant vaccines developed by AstraZeneca and the University of Oxford. Health Canada has reviewed the manufacturing information for these vaccines and found them to be comparable.

1. Are COVID-19 vaccines safe for cancer patients?

COVID-19 vaccines use either conventional or novel mechanisms of action to safely elicit immune responses. Conventional platforms include recombinant viral proteins, live attenuated vaccines and inactivated vaccines, while novel methods include viral vector-based vaccines and mRNA-based vaccines.8

The COVID-19 vaccine is safe for use in cancer patients. Based on observational studies, the safety profile of mRNA vaccines in the immunocompromised population, including patients with cancer, has been comparable to what has been observed in the general population, with no unexpected or serious safety signals to date.17 Additionally, prior experience with other protein-based or inactivated vaccines have not reported unique or major side effects in immunocompromised patients.7 The most frequently reported side effects of COVID-19 vaccine candidates were usually mild or moderate and include pain at the site of injection, fatigue, headache, myalgias and fever (see question 9 below). Live attenuated vaccines carry the risk of disease caused by vaccine strains and are not recommended during and after immunosuppressive therapy (such as chemotherapy).1
Currently, these are the vaccines available for use in Ontario for active immunizations to prevent COVID-19:

- Pfizer COVID-19 mRNA vaccine (Tozinameran or BNT162b2)
- Moderna COVID-19 mRNA vaccine (mRNA-1273 SARS-CoV-2)
- AstraZeneca COVID-19 non-replicating adenovirus vaccine (AZD1222 or ChAdOx1-S recombinant)

The Pfizer and Moderna vaccines are authorized for use in individuals 12 years of age and older, while the AstraZeneca vaccine is authorized for use in individuals 18 years of age and older. Refer to local public health guidance for recommendations on which vaccine to use for specific age groups.

The Pfizer, Moderna and AstraZeneca vaccines are administered intramuscularly as a series of two doses. The recommended immunization schedules of the 2-dose COVID-19 vaccines are listed in Table 1. NACI recommends that an additional dose of an authorized mRNA COVID-19 vaccine should be offered to **moderately to severely** immunocompromised patients in the authorized age groups.\(^\text{17}\)

(For details on additional doses after completing a 2-dose COVID-19 vaccine series, refer to question 7: Should an additional dose of COVID-19 vaccine be considered in patients with cancer?)

</tbody>
</table>

\(^a\)While efforts should be made to vaccinate according to the authorized schedules as per individual vaccine product monographs, extended vaccination intervals may be considered in the context of limited vaccine supply; however, they may not be appropriate in certain patient populations, as described above.\(^\text{13,15}\)

\(^b\)A 12-week interval is preferred for the AstraZeneca COVID-19 vaccine based on available ad hoc analyses of the vaccine clinical trial interval data; efficacy may be lower if interval is less than 12 weeks, in the general population.

The following patient groups should receive the COVID-19 vaccine at the dose interval recommended by the manufacturers:\(^\text{15}\)

- Transplant recipients (including solid organ transplants and hematopoietic stem cell transplants).
- Patients receiving active treatment (chemotherapy, targeted therapies, immunotherapy, excluding individuals receiving solely hormonal therapy or radiation therapy) with:
  - Malignant hematologic disorders
  - Non-hematologic malignant solid tumors

Refer to the latest NACI and Ministry of Health recommendations on the use, dosing interval and interchangeability of approved COVID-19 vaccines.
Both the Moderna and Pfizer vaccines use COVID-19’s genetic code in the vaccine, exploiting the host cell to translate the code and make the target spike protein, eliciting both neutralizing antibody and cellular immune responses.\(^4\) The AstraZeneca COVID-19 vaccine uses replication deficient adenovirus vectors, to deliver the COVID-19 spike protein genetic sequence into the host cell, locally stimulating neutralizing antibody and cellular immune responses.\(^{11,12,14}\) As there is no whole, live or replicating virus involved, the vaccines cannot cause disease and, therefore, may be administered to cancer patients after a risk-benefit assessment by the cancer health care team. It is important to note that immunocompromised persons, including individuals receiving immunosuppressant therapy, may not produce a full antibody response and should therefore continue to follow Public Health guidance to avoid exposure, unless otherwise advised by their health care team.\(^{10}\)

*Please see Appendix for a complete list of references.*

2. **What are the contraindications to the COVID-19 vaccines?**

The Pfizer, Moderna and AstraZeneca COVID-19 vaccines are contraindicated in individuals who are hypersensitive to the active substance or to any ingredient in the formulation.\(^{1,2,3,4}\)

The AstraZeneca vaccine is contraindicated in patients who have experienced major venous and/or arterial thrombosis with thrombocytopenia after vaccination with AstraZeneca COVID-19 vaccine. It is also contraindicated in those who have previously experienced episodes of capillary leak syndrome (CLS) as some fatal cases have been observed very rarely following administration of the AstraZeneca vaccine.\(^3\)

Refer to the product monographs for the complete description of contraindications.

*Please see Appendix for a complete list of references.*

3. **Which patient factors require further consideration before giving a COVID-19 vaccine?**

Patients with a history of severe allergy (e.g., anaphylaxis) to the COVID-19 vaccine or any of its components, including PEG, polysorbate or tromethamine should be referred to an allergist/immunologist to determine if the vaccine can be safely administered.\(^1\) See question 10: “Can a cancer patient receive the COVID-19 vaccine if they have allergies?” for more information.

Patients who have experienced a previous cerebral venous sinus thrombosis (CVST) with thrombocytopenia or heparin induced thrombocytopenia (HIT) should only receive the adenovirus-based vaccine if the potential benefits outweigh the potential risks.\(^2,3\) A combination of thrombosis and thrombocytopenia, in some cases accompanied by bleeding, has been observed very rarely following vaccination with adenovirus-based vaccines. See question 9: “What are possible side effects of the vaccination?” for more information.

Patients who have experienced major venous and/or arterial thrombosis with thrombocytopenia following vaccination with the AstraZeneca COVID-19 vaccine should not receive a second dose of the AstraZeneca COVID-19 vaccine.\(^4\)

*Please see Appendix for a complete list of references.*
4. Which cancer patients are at a higher risk of becoming infected with COVID-19 and/or having severe complications with COVID-19?

Cancer patients have a higher risk of contracting COVID-19 and some cancer patients are at higher risk for poorer outcomes with the infection. The following patients are at a higher risk:

- Patients with **hematological cancers**
- Patients with **lung cancer**
- Patients who were **diagnosed with cancer within the last year**
- Patients who have had a **stem cell transplant within the last 6 months**
- Patients with **active cancer**, defined as:
  - metastatic disease and/or
  - receiving or recently completed cancer-directed **systemic treatment, radiation therapy**, or **surgical resection**

Also consider the following patient factors when determining risk:

1. **Time since diagnosis:**
   Patients with a recent diagnosis (within the last year) especially those with a hematologic malignancy have an increased risk of mortality with COVID-19 compared to those with a less recent diagnosis. Patients with a diagnosis 1 to 5 years prior have a higher risk of mortality than patients with a diagnosis beyond 5 years. Patients with hematologic malignancy or following allogeneic stem cell transplant may remain at high risk of infection and mortality even beyond 5 years, as they are often on a prolonged course of treatment or have ongoing significant immunosuppression.

2. **Cancer type:**
   In general, patients with hematologic cancers who are at any stage of treatment (especially those ≥ 60 years of age) and patients with lung cancer have a higher risk of mortality compared to patients with other cancer diagnoses.

3. **Treatment type:**
   There is some evidence to suggest that patients who are currently or recently (within the last 6 months) treated with immune checkpoint inhibitors are at a higher risk of mortality; however, the population-based data are likely to be influenced by a number of confounding factors. A retrospective study of adult patients with lymphoma identified an association with prolonged hospitalization due to symptoms and a higher risk of death from COVID-19 in patients who were recently treated (within 12 months) with anti-CD20 therapy. Other studies were unable to demonstrate whether systemic treatment types (such as chemotherapy and targeted therapy) increase the risk of mortality from COVID-19. In a population-based study, however, patients with active cancer, particularly those on active treatment, were associated with higher rates of hospitalization, ICU admission, and 30-day mortality. In addition, patients on active treatment may be at an increased risk of neutropenia and development of infections. Patients who have had a stem cell transplant within the last 6 months are also considered to be higher risk.
4. Other factors:
   (a) Older patients (≥ 65) are at higher risk of mortality compared with younger patients.
   (b) Patients who have recently had neutropenia (within 90 days) and patients with lymphopenia at
time of COVID-19 diagnosis are at a higher risk of mortality.
   (c) Patients who smoke or have other comorbidities, including obesity, may be at risk for increased
hospitalizations and mortality. Follow local public health advice to determine risk based on non-
cancer related factors.
   (d) Consideration of COVID-19 vaccination should be given to household or close contacts of cancer
patients at higher risk of infection/mortality (based on public health guidance) to reduce the risk
of exposure to the virus.

Rationale:

Current available data suggest that COVID-19 mortality is higher in patients with cancer than in the general
population.1,2,3,4,5,14,15 A pooled analysis of 18,650 found the probability of death to be 25.6% in patients with
both a COVID-19 and cancer diagnosis.3 A multivariate analysis of over 10,000 COVID-19 deaths from the UK
found that, relative to patients without cancer, patients with nonhematologic malignancy diagnosed within
one year prior to a COVID-19 diagnosis had a 1.8-fold higher risk of death, and a hematologic malignancy
carried a fourfold higher risk.5 The risks were lower for patients diagnosed with cancer 1 to 4.9 years prior to
COVID-19 when compared those diagnosed within the preceding year; however, risk was still elevated
compared with people without cancer. Beyond five years, risks for death remained elevated for those with
hematologic but not for those with nonhematologic malignancies.5

Most studies show a higher risk of mortality among patients with hematologic and lung cancers.1,6,7,16 A
small Chinese study suggested that lung cancer, metastatic disease, and hematologic malignancy may be
associated with higher rates of COVID-19–related death and intensive care unit (ICU) admission.6 A larger
study of 309 cancer patients with a diagnosis of COVID-19 found that hematologic malignancies were
associated with increased COVID-19 severity and patients with lung cancer demonstrated higher rates of
severe or critical COVID-19 events.1

Adults with hematologic cancers are reported to be at high risk for progression to severe disease and death
from COVID-19, with an estimated mortality of 36% or greater.19

An analysis of 536 Italian patients with hematologic malignancy and COVID-19 found that mortality was
significantly higher than in the general Italian population with COVID-19, regardless of age.7 A large meta-
analysis found the risk of death among adults with hematologic malignancies (n = 3240) was 34 percent, and
patients ≥60 years of age had a significantly greater risk of dying than did younger patients (relative risk [RR]
1.82, 95% CI 1.45-2.27).8

A multi-institutional international registry study including 400 patients with thoracic cancer also diagnosed
with COVID-19 showed that many patients were hospitalized (78%), and 36 percent of patients died.9,10
Patients who had received chemotherapy within three months had a higher risk of dying from COVID versus
patients who did not (hazard ratio 1.7, 95% CI 1.1-2.6); however, in univariate analysis, there were no factors
that were identified, including active cancer treatment, as being associated with mortality.10

Recent active oncologic therapy did not appear to increase the risk of mortality from COVID-19 in some
studies. Jee et al reported that cytotoxic chemotherapy was not significantly associated with a severe or
critical COVID-19 event and a systemic review indicated that there was no association between receipt of a particular type of oncologic therapy and mortality.4 Patients on active immunosuppressive therapy (such as chemotherapy) are, however, more likely to be neutropenic and are at a high risk of developing infection.12 Robilotto et al analysed 423 patients with cancer and COVID-19 and found that age older than 65 years and treatment with immune checkpoint inhibitors (ICIs) were predictors for hospitalization and severe disease, whereas receipt of chemotherapy and major surgery were not. In this study, treatment with ICI predicted both hospitalization and severe disease, although there was considerable heterogeneity in ICI-treated tumor types, and disease-specific factors could not be individually addressed.11 A more recent retrospective study looked at adult lymphoma patients (n=111) who were admitted to hospital for COVID-19. The median length of admission was 14 days (range,1–235) and the 6-month overall survival was 69%. In multivariable analyses, recent administration of anti-CD20 therapy (within 12 months) was associated with prolonged hospitalization (sub-distribution hazard ratio 2.26, 95% confidence interval 1.42–3.6, p < 0.001) and higher risk of death (hazard ratio 2.17, 95% confidence interval 1.04–4.52, p = 0.039). An age ≥70 years and relapsed/refractory lymphoma were also associated with prolonged hospitalization and decreased overall survival.21

Garassino reviewed evidence around ICIs and COVID outcomes, which included further analysis of the Robilotto data. It was concluded that there is insufficient evidence at this time to suggest that ICIs worsen complications from COVID-19 and that the population-based registries reporting on the incidence of COVID-19 in patients with cancer receiving ICI therapy compared with patients with cancer not receiving ICI or individuals without cancer, are likely to be plagued by multiple confounding factors.

A recent population-based study with 323 patients enrolled prior to the pandemic (n=67 cancer patients; n= 256 non-cancer patients) compared COVID-19 outcomes. After adjusting for demographics, smoking status, and comorbidities, a diagnosis of cancer was independently associated with higher odds of hospitalization (odds ratio = 2.16, 95% confidence interval = 1.12 to 4.18) and 30-day mortality (odds ratio = 5.67, 95% confidence interval = 1.49 to 21.59). Notably, older age, Black race, and number of comorbidities were statistically significantly associated with increased odds of hospitalization and ICU admission (all P<.05). In addition, exploratory subgroup analyses were performed to investigate these associations among patients with active cancer (defined as having metastatic disease and/or receiving cancer-directed systemic therapy, radiation therapy, or surgical resection in the 2 months before COVID-19 diagnosis) compared with noncancer patients, as well as those with cancer in remission compared with noncancer patients. The analyses showed that adjusted associations with hospitalization, ICU admission, and 30-day mortality were strongest in the active cancer patient group. The authors concluded that patients with cancer, particularly those receiving active treatment, should be among groups specifically targeted for COVID-19 mitigation and prevention strategies such as vaccination.14

Lymphopenia at COVID-19 diagnosis was associated with higher rates of severe critical illness.1 Patients with baseline neutropenia 14-90 days before a COVID-19 diagnosis had worse outcomes.1 In addition, current literature suggests that the likelihood of a severe illness and death from COVID-19 is higher among adult patients with cancer who have other comorbidities, including obesity.2

Please see Appendix for a complete list of references.
5. When will cancer patients receive immunity (mount an immune response) after the COVID-19 vaccine?

In the general population, individuals may not receive optimal protection until after the vaccine series is completed. Immunocompromised individuals were initially excluded from the earlier Phase 2/3 vaccine clinical trials. More recently, studies have indicated that after a full vaccine series, patients with solid tumours demonstrate high rates of immune response; though, immune response may be diminished compared to the general public.

Evidence suggests that patients with hematologic malignancies mount blunted and highly variable antibody responses after completing the two-dose mRNA COVID-19 vaccine series. This is a result of both their underlying condition and treatments affecting the efficacy of COVID-19 vaccines. In addition to active treatment within the last 6-12 months with BTKIs (Bruton tyrosine kinase inhibitors) and anti-CD20 antibody therapies, ruxolitinib and venetoclax treatments also negatively affected antibody response, rendering these patients sub-optimally protected from COVID-19. Patients on immunomodulators, proteosome inhibitors (or both) mount poorer antibody responses than do untreated patients with hematological malignancies. There are other treatments that may result in a reduced antibody response. Although immune response may be sub-optimal, COVID-19 vaccination still offers some protection, and some protection is better than none.

To optimize immune response, individuals on active treatment for malignant hematologic disorders and non-hematologic malignant solid tumors, excluding individuals receiving solely hormonal therapy or radiation therapy, should receive the COVID-19 vaccine at the dose interval indicated in the product monograph. For moderately to severely immunocompromised patients, an additional dose may be required. For details on additional doses after completing a 2-dose COVID-19 vaccine series, refer to question 7: Should an additional dose of COVID-19 vaccine be considered in patients with cancer?

Patients should continue to follow Public Health guidance to avoid exposure to COVID-19, unless otherwise advised by their health care team. To protect those who are immunocompromised, it also is strongly recommended that all people that come into close contact (e.g., family, friends, caregivers) with these individuals are fully vaccinated according to public health guidelines.

Please see Appendix for a complete list of references.

6. When is the optimal time for cancer patients to receive the COVID-19 vaccine?

Ideally, vaccination should occur at a time when patients are least likely to be immunocompromised as vaccine efficacy will depend on patients’ ability to mount a response to the vaccine. Based on experience with the flu vaccine and real-world evidence with COVID-19 vaccines, response rates can be highly variable, and the effectiveness of the vaccine will depend on underlying disease as well as the type and timing of treatment that could hinder a patient’s ability to mount an immune response.
The following guidance on the timing of the COVID-19 vaccine administration, in relation to treatment for cancer patients has been adapted from information pertaining to the inactivated influenza vaccine and will be updated as new evidence emerges.

**General guidelines:**
- Clinical judgement should be exercised around administration of the complete series of the vaccine prior to initiation of systemic treatment (chemotherapy or immunotherapy). Prioritization of systemic treatment over vaccination, or vice versa, should be determined via risk assessment, considering factors such as patient’s age, comorbidities, treatment intent, type of treatment, etc.
- When feasible, vaccines should be administered at least 2 weeks before initiation of systemic treatment to optimize immunogenicity.1,2,4,20
- For COVID-19 vaccines given as a 2-dose series:
  - If the complete series of the vaccine cannot be administered 2 weeks before the start of treatment, the first dose of the vaccine should be administered at least 2 weeks before initiation of systemic treatment, and the second dose within a few days prior to administration of systemic treatment. Although evidence around timing with systemic treatment varies, this can minimize uncertainty around the cause of flu-like symptoms or infusion-related reactions if vaccine is administered around the day of systemic treatment.5,6,20,21
  - If the second dose cannot be administered within a few days of systemic treatment administration, a risk assessment should be conducted around prioritization of either the treatment schedule or vaccination schedule, with consideration for factors such as patient’s age, comorbidities, treatment intent, type of treatment, etc.
  - If administration of the second dose of the vaccine is delayed, it should be administered as soon as possible.19
- Patients receiving vaccine during treatment may have an attenuated or absent response to the vaccine and should continue to exercise precautions when possible (wearing a mask when unable to maintain social distance etc.).1,2,4,20 An additional dose of COVID-19 vaccine may be required.33
- Patients who are not on active treatment may receive the vaccine after an appropriate time has passed since their last treatment was completed, depending on the agents used.

**Cytotoxic Chemotherapy**
- If feasible, allow at least two weeks to pass after the second vaccine dose before starting cytotoxic therapies to allow for memory T cell formation.22
- During active chemotherapy treatment, all doses of the vaccine should be administered, at minimum, within a few days prior to next chemotherapy cycle, if feasible (i.e. when immunosuppressive effects of cytotoxic chemotherapy are at their lowest and not on the same day of chemotherapy).5,6,20
- Immunization in patients receiving chemotherapy when blood counts are low is discouraged.13,14
- Induction Chemotherapy for Leukemia:
  - Vaccine should be given at least 2 weeks prior to the start of immunosuppressive therapy or when effects of immunosuppressive therapy are at the lowest level.2
  - If the vaccine cannot be given prior to start of induction treatment in acute leukemia, it may be given upon blood count recovery, prior to the start of consolidation treatment.

**Targeted therapy**
• Vaccines may be administered at any time during treatment for most targeted therapies. Consideration for timing should be taken for targeted treatments that may cause neutropenia or lymphopenias.\textsuperscript{3,20}

Immunotherapy

• Monoclonal antibodies:
  o If feasible, allow at least two weeks to pass after the second vaccine dose before starting B-cell depleting therapies to allow for memory T cell formation.\textsuperscript{22}
  o Patients receiving maintenance rituximab may receive vaccine at any time during treatment; although there may be a reduced response, extrapolated evidence suggests it is unlikely to cause harm.\textsuperscript{7,20}

• Immune checkpoint inhibitors (ICI):
  o Many trials using ICI do not allow vaccinations due to a concern of increased autoimmune events. However, evidence with inactivated influenza vaccine suggests that patients receiving ICI therapy may not experience an increase in immune-related adverse events when they receive the vaccine within 2 months of treatment.\textsuperscript{9,10} Recent research with mRNA vaccines supports this. Cancer patients treated with ICI who received mRNA vaccine were not likely to develop new immune-related side effects or exacerbation of existing immune-related side effects in the short-term.\textsuperscript{31}
  o For patients receiving a combination of ICI, the risk of increased autoimmune events is uncertain and should be weighed against the definite risk of a patient potentially contracting COVID. Experience with vaccinations in this population is mostly with the influenza vaccine and more data will need to be collected before any further recommendations can be made.

Radiation Therapy

• Patients who are receiving radiation therapy alone (not in combination with chemotherapy) may receive vaccine at any time during treatment.\textsuperscript{20}

Stem cell transplant

• If feasible, both doses of the vaccine should be administered at least 2 weeks before initiation of a transplant conditioning regimen, and at least 2 weeks prior to stem cell collection for donors.\textsuperscript{2}
  • Post-transplant, the vaccine may be administered as early as 3 months after transplant.\textsuperscript{12,18,22,24}

CAR T-Cell Therapy

• If feasible, both doses of the vaccine should be administered at least 2 weeks before CAR T-cell therapy.\textsuperscript{18}
  • Vaccines should not be administered until at least 3 months after completion of therapy.\textsuperscript{22,25}

Corticosteroids

• If feasible, the vaccine should be administered after corticosteroid treatment has been completed or reduced to ≤ 10 mg/day of prednisone or equivalent, due to the immunosuppressive nature of corticosteroids.\textsuperscript{32}

Surgery
• Essential urgent surgery should take place, irrespective of vaccination status. Non-urgent elective surgery can also take place soon after vaccination. There is some rationale for separating the date of surgery from vaccination by a few days (at most 1 week) so that any symptoms such as fever might be correctly attributed to the consequences of either vaccination or the operation itself. For surgeries inducing immunosuppression (e.g. splenectomy), a wider window (e.g. 2 weeks) may be recommended.

Cancer Screening
• Since lymphadenopathy is a potential COVID-19 vaccine side effect, screening exams should be conducted before the first dose of a COVID-19 vaccine or 4–6 weeks after the second dose of a COVID-19 vaccine if feasible, and when it does not unjustifiably interrupt management.

See question 7: “Should an additional dose of COVID-19 vaccine be considered in patients with cancer?” for information around timing of third doses.

Please see Appendix for a complete list of references.

7. Should an additional dose of COVID-19 vaccine be considered in patients with cancer?

Studies have shown decreased immunogenicity in some immunocompromised adults, including patients with malignancy (solid tumour and hematological), when compared to healthy vaccine recipients. Emerging data suggest that an additional COVID-19 vaccine dose in immunocompromised patients enhances antibody response and increases the proportion of patients who respond.

NACI recommends that an additional dose of an authorized mRNA COVID-19 vaccine should be offered to moderately to severely immunocompromised patients in the authorized age groups.

An additional dose of a viral vector vaccine should only be considered when other authorized COVID-19 vaccines are contraindicated or inaccessible. Informed consent for an additional dose of viral vector vaccine should include discussion about its lack of evidence as an additional dose in this population, and the increased risk of Vaccine-Induced Immune Thrombotic Thrombocytopenia (VITT), Capillary Leak Syndrome (CLS), and Guillain-Barre syndrome (GBS) following viral vector COVID-19 vaccines.

Moderately to severely immunocompromised cancer patients include those who:

- Are on active treatment for solid tumour or hematologic malignancies that can cause moderate to severe immunosuppression.
  - Active treatment is defined as chemotherapy, targeted therapies, immunotherapy, and excludes individuals receiving therapy that does not suppress the immune system, e.g. solely hormonal therapy or radiation therapy
  - Active treatment includes patients who have completed treatment within 3 months, or within 12 months for patients receiving B-cell depleting therapy.
- Are on active treatment with the following categories of immunosuppressive therapies: anti-B cell therapies (monoclonal antibodies targeting CD19, CD20 and CD22, e.g. rituximab, obinutuzumab), high-dose systemic corticosteroids (prednisone equivalent of \( \geq 20 \text{ mg/day} \)), alkylating agents (e.g.}
bendamustine, cyclophosphamide), antimetabolites (e.g. 5-fluorouracil, methotrexate), or tumour-necrosis factor (TNF) inhibitors (e.g. infliximab) and other biologic agents that are significantly immunosuppressive.

- Are recipients of chimeric antigen receptor (CAR)-T-cell therapy or hematopoietic stem cell transplant (within 2 years of transplantation or taking immunosuppression therapy)

Refer to the latest NACI recommendations for definition of moderately to severely immunocompromised non-cancer populations.

Ontario guidelines recommend an interval of at least 2 months (8 weeks) between the last dose of the 2-dose series and the third dose. As per NACI, the minimum interval should be 28 days; an interval longer than the minimum 28 days between doses is likely to result in a better immune response. If a longer interval is being considered, then risk factors for exposure (including local epidemiology and circulation of variants of concern) and risk of severe disease should also considered.13, 14

Refer to the latest NACI recommendations and local public health guidance for detailed information on eligibility criteria and timing of additional COVID-19 vaccine doses.

Patients should continue to follow Public Health guidance to avoid exposure to COVID-19, unless otherwise advised by their health care team. To protect those who are immunocompromised, it also is strongly recommended that all people that come into close contact (e.g., family, friends, caregivers) with these individuals are fully vaccinated according to public health guidelines.

Please see Appendix for a complete list of references.

8. **When should the COVID-19 vaccine be given in relation to other vaccinations?**

mRNA and non-replicating viral vector vaccines (e.g., Pfizer, Moderna, AstraZeneca) are not live vaccines and can neither cause infection nor change the host’s DNA. There is no data on the co-administration of COVID-19 vaccines with other vaccines. In order to maximize the benefits of COVID-19 vaccines and minimize risks (e.g., immune interference, uncertainty around the cause of side effects), COVID-19 vaccines should not be given simultaneously with other vaccines.1

Do not administer any other vaccine until at least 28 days after each vaccine dose of an mRNA or viral vector COVID-19 vaccine, except in the case where another vaccine is required for post-exposure prophylaxis. If the COVID-19 vaccine is given after another vaccine, there should be a wait period of at least 14 days.1

Please see Appendix for a complete list of references.
What are possible side effects of the vaccination?

Side effects of the COVID-19 vaccines were usually mild or moderate and generally resolved in a few days.\textsuperscript{1,4,6,7,10,11,12} Local reactions for the vaccines included pain, rash, redness or swelling at the injection site.\textsuperscript{2,7,11,12,16} Delayed local reactions have been reported.\textsuperscript{15} Systemic side effects included fatigue, headache, muscle/joint pain, diarrhea, chills, fever and nausea/vomiting.\textsuperscript{2,7,11,12,16}

Frequencies of systemic effects for the mRNA COVID-19 vaccines were generally higher after the second dose, and in patients < 56 years of age for the Pfizer vaccine and between 18 to 64 years for the Moderna vaccine.\textsuperscript{2,3,7,8}

Preliminary data demonstrate side effects after the 3rd dose of an mRNA vaccine were similar to that of the two-dose series: fatigue, headache, muscle/joint pain and pain at injection site were the most commonly reported side effects, and overall, most symptoms were mild to moderate.\textsuperscript{30,31} No worsening of underlying disease was reported after immunization.\textsuperscript{33} No serious adverse events were deemed to be associated with the additional vaccine dose. The impact of additional doses on rare adverse events, including myocarditis/pericarditis, are unknown.\textsuperscript{33}

For the AstraZeneca vaccine, fewer and milder adverse reactions were reported after the second dose and reactogenicity reduced with increasing age.\textsuperscript{3,10,11}

Patients should be educated to seek medical attention if the symptoms last longer than 48-72 hours, due to the similarity with symptoms of COVID-19 or other infections.

Cases of lymphadenopathy occurring in the arm and neck region\textsuperscript{24,28} have been reported post COVID-19 vaccination, which may mimic metastasis. Vaccine-related lymphadenopathy typically occurs within 7 days of vaccination and generally subsides by 12-14 days. However, vaccine-related lymphadenopathy may persist as far as 4-6 weeks after vaccine administration.\textsuperscript{17,21,22,23,26,27} The peak of lymph node activity tends to be earlier after the second vaccination as compared to the first vaccination.\textsuperscript{27} Consider timing of vaccination when assessing patients with new or worsening lymphadenopathy.\textsuperscript{2,7,11,12,13,14,23}

Very rare cases of moderate-to-severe thrombocytopenia and thrombotic complications at unusual sites (e.g., abdomen, splanchnic vein, sinus or cerebral vein), called vaccine-induced immune thrombotic thrombocytopenia (VITT), have been reported with the AstraZeneca COVID-19 vaccine (some emerging reports with Pfizer or Moderna vaccines in the United States).\textsuperscript{3,12,23,25,34,35} In some cases, these have been accompanied by bleeding.\textsuperscript{12} VITT typically occurs within 3 weeks following AstraZeneca vaccine administration.\textsuperscript{12} Fatalities have been reported. The exact mechanism is still under investigation but appears to be similar to heparin-induced thrombocytopenia (HIT). It is associated with platelet activating antibodies, which stimulate clot formation and thrombocytopenia. Patients should be advised to seek immediate medical attention if they develop symptoms of thromboembolism accompanied by thrombocytopenia, which becomes clinically apparent approximately 4-28 days after receiving a viral vector COVID-19 vaccine and should be monitored for symptoms up to 42 days.\textsuperscript{3,12,18-20,23,25} Close monitoring of patients with previous thrombocytopenia is highly recommended as VITT can develop earlier than the expected onset in patients with a history of thrombocytopenia and worsen pre-existing thrombocytopenia.\textsuperscript{32}
Very rare cases of myocarditis and/or pericarditis following vaccination administration of mRNA vaccines have been reported.\textsuperscript{2,3,7} The onset of symptoms (including chest pain, shortness of breath and palpitations) have occurred within a few days following receipt of the mRNA vaccines and cases have occurred more commonly after the second dose, in adolescents, young adults and male patients.\textsuperscript{3} Available short-term follow-up data suggest that the symptoms are generally mild and resolve in most individuals, but information on long-term sequelae is lacking. Patients receiving an mRNA vaccine should be informed about the very rare risk of myocarditis and/or pericarditis following immunization and individuals who experienced this adverse effect after a first dose of an mRNA vaccine should defer their second dose until more information is available.\textsuperscript{3} Cardiology consultation for management and follow up should be considered.\textsuperscript{2,3}

Bell’s Palsy (typically temporary weakness or paralysis on one side of the face) has been reported very rarely after the use of mRNA COVID-19 vaccines. The exact cause is unknown, with symptoms appearing suddenly and generally starting to improve after a few weeks. It is believed to be due to swelling and inflammation of the nerve that controls muscles on one side of the face.\textsuperscript{29}

Very rare events of demyelinating disorders, such as Guillain-Barré Syndrome, have been reported after vaccination with the AstraZeneca COVID-19 Vaccine.\textsuperscript{12}

Please see Appendix for a complete list of references.

10. Can a cancer patient receive the COVID-19 vaccine if they have allergies?

Severe allergic reactions to the vaccine have been reported.\textsuperscript{1,2,4, 12, 13}

Patients with a history of severe allergy (e.g., anaphylaxis) to any of the components of a COVID-19 vaccine should be referred to an allergist/immunologist to determine if the vaccine can be safely administered.

Patients who have had an allergic reaction within 4 hours of receiving a previous dose of a COVID-19 vaccine should not receive a second dose unless they have been evaluated by an allergist/immunologist and it is determined that the vaccine can be safely administered. Documentation of the discussion with the allergist/immunologist must be provided to the healthcare provider administering the vaccine and it should include a vaccination care plan.\textsuperscript{15}

Polyethylene glycol (PEG), a water-soluble polymer used as a drug delivery vehicle, is a component of both Pfizer and Moderna vaccines and is known to cause mild to severe hypersensitivity reactions.\textsuperscript{6,7} Patients who have had anaphylactic reactions to PEG should be referred to an allergist/immunologist to determine if any of the vaccines can be safely administered.\textsuperscript{15} Cancer medications containing PEG include (but are not limited to) the following:

1. PEGaspargase (Oncaspar®)
2. Pegfilgrastim (e.g., Neulasta® and others)
3. Liposomal irinotecan (Onivyde®)
4. PEG-liposomal doxorubicin (Caelyx®)

Polysorbate, a surfactant and emulsifier used as an excipient in some drug formulations,\textsuperscript{7} is structurally related and has the potential for cross-reactivity to PEG. It is also a component of the AstraZeneca vaccine.\textsuperscript{12} Patients who have had an anaphylactic reaction to polysorbate should be referred to an
allergist/immunologist to determine if any of the vaccines can be safely administered. Cancer medications containing polysorbate include (but are not limited to) the following:

1. Cabazitaxel
2. Docetaxel
3. Etoposide
4. Fosaprepitant (IV)
5. Rituximab (reactions with rituximab are typically a result of cytokine release syndrome and may not be related to polysorbate)
6. Paclitaxel (contains the excipient, Cremophor EL (polyethoxylated castor oil) which has the potential for cross-reactivity with polysorbate)

Not all medications that contain PEG or polysorbate will cause allergic reactions and many drugs, including oral medications, may contain PEG or polysorbate in various concentrations, depending on the manufacturer.

Tromethamine is a component of the Moderna vaccine and may cause allergic reactions. It is also a component in contrast media and some oral and parenteral medications (e.g., ketorolac).

Clinicians should consult individual product monographs for a full list of non-medicinal ingredients if their patients have had a history of anaphylactic reactions to their cancer medications. Patients should be counseled about the risks of developing a severe allergic reaction against the benefits of vaccination.

Refer to Ministry of Health guidance on COVID-19 vaccines and allergies for more information.

Please see Appendix for a complete list of references.

If you have any questions regarding the COVID-19 Vaccine and cancer, please email the Drug Formulary team at OH-CCO_DrugFormulary@ontariohealth.ca.
